Chapter 7

Detector commissioning

In the course of 2019, the commissioning of the SuperNEMO demonstrator has begun and first calorimeter data were taken.

The calorimeter of SuperNEMO is segmented in 712 optical modules (OM), each composed by a coupling between a photomultiplier tube (PMT) and a polystyrene scintillator bloc (see sec. 3.1.5 for more details). The divider of a PMT is connected to 2 cables, one providing the high voltage (HV), the other one, called signal cable, is a coaxial cable collecting and transporting the charge provided by the PMT.

By the summer 2020, the SuperNEMO demonstrator will be encapsulated in an anti radon tent. The so called *patch panel* will insure passage of cables from the inside, to the outside of the anti radon tent, therefore doubling the amount of cables needed for the calorimeter. We refer to the cables running from detector to patch panel as *internal* cables, and the cables from patch panel to the electronic boards as *external* cables. Consequently, regarding only the calorimeter part, 2848 cables were cut, assembled, connector-mounted, transported and installed at LSM. Then the check of every cable condition is mandatory to control and eventually fix them.

7.1 Reflectometry analysis

7.1.1 Goal of the reflectometry analysis

Taking into account the final demonstrator design, each coaxial length was determined, cables were cut and labelled in LAL, Orsay. All external coaxial cables were designed to be 7 meters-long – the distance between electronic boards and patch panel being the same for all channels at electronic boards – and internal cable lengths have been adapted to fit the distance from the patch panel to each optical module. Then, cutting and labelling all cables lasted several weeks. After all cables were transported and installed at LSM, we had to check each coaxial cable condition, for several reasons:

Figure 7.1: A representation of pulses sent in a cable for the reflectometry analysis is given. The electronic boards are symbolised by the black chip, and the patch panel by the red vertical bar. Three scenarios where a primary pulse is sent in one cable (represented in grey), are represented. (a) The cable is well connected at the patch panel and at the PMT. The signal reflects at the PMT divider. (b) The cable is not connected at PMT and the signal is reflected at the end of the cable. (c) The cable is not connected at patch panel and the signal is reflected at the end of the external cable.

- check if no cable was damaged during the transport and the installation;
- control if no swap between cables has been made during cable labelling or calorimeter cabling,
- check if the coaxial cable was cut at the right length,
- more importantly estimate the signal time delay due to the cable lengths: knowing that the velocity of electrons in the coaxial cables has a known constant value, the longer is the cable, the more the signal takes time to travel from the PMT to the electronic channel. Therefore, each coaxial cable length has to be characterised, especially if we want to do time coincidences between two signals in two different channels.

To do so, a pulse, called *primary* pulse, is generated at the electronic board readout. The signal will travel all along the coaxial cable, from the electronic board to the PMT divider. Whether the cable is correctly connected to the PMT or not, the signal reflects at the other end. Then the signal travels back from the PMT to the electronic board channel, where it is recorded by the acquisition. We called this recorded reflected pulse *secondary* pulse. An example of the total recorded signal is displayed in Fig. 7.3. In order to accumulate enough statistics, we send thousands of pulses in each coaxial cable. The analyses of the shape and of the arrival time of those secondary pulses for each channel is called *reflectometry*, and allow us to check the coaxial cable conditions and to control their lengths.

7.1.2 Pulse timing: controlling cable lengths

The first step of this analysis is to experimentally determine the length l_j^m for all signal cables j installed on the demonstrator. This length is defined as

$$l_j^m = 0.5 t_j v_p, \quad (7.1)$$

Figure 7.2: Three different lengths l_j of cables are measured. Pulses are sent inside all cables. The lengths l_j are plotted as a function of the time differences t_j between primary and secondary pulses. The value of v_p/c fitted from the data points is displayed. This value of 0.697 ± 0.0011 shows the compatibility with the one supplied by the constructor, of $0.69 c$.

where t_j stands as the time made by the electrons to do a round trip between one electronic channel and one PMT, and v_p is the velocity of electrons in the coaxial cables, which can be expressed as a fraction of light speed in vacuum, c . The time difference t_j between the primary pulse and the secondary pulse is written as

$$t_j = \langle t_{\text{secondary pulse}} - t_{\text{primary pulse}} \rangle_p, \quad (7.2)$$

$\langle \rangle_p$ being the average over all pulses sent in one single cable j . The velocity v_p is supplied by the cable manufacturer as

$$v_p = \frac{c}{\sqrt{\epsilon_r}},$$

with ϵ_r the relative dielectric constant of the material. Therefore, this celerity depends on the components. For the coaxial cables chosen in the demonstrator design, the data sheet of the cable gives $v_p = 0.69 c$. A study is performed to verify experimentally the value of v_p . Three cables of different lengths are measured with a precision of 1 cm. A thousand of primary pulses are sent in each of the three cables, then the time for each secondary pulse is recorded. At the end, we have three independent measures of the velocity v_p in the used coaxial cables. On Fig. 7.2 is displayed the lengths l_j as a function of the times t_j . The fitted value of $v_p/c = 0.697 \pm 0.0011$ is displayed and shows a compatibility up to 7σ with the data sheet.

Figure 7.3: In black is shown an example of a total recorded waveform with the primary pulse (left) and secondary the pulse (right). A representation of time computed with a Constant Fraction Discriminator (CFD) is given for the secondary pulse. Its maximal amplitude (red dotted line) and its fraction for $f = 40\%$ (green dotted line) are displayed. The time T_{pulse} (orange dotted line) represents the time of arrival of the secondary pulse computed with CFD, with the fraction $f = 40\%$.

As we want to determine the time interval t_j , we have to define what is the *time* of a pulse. In this analysis, we use a technique called Constant Fraction Discriminator (CFD), providing an amplitude-independent information about time of a pulse. This algorithm aims at tracking a signal and defining its time arrival at a given fraction f of its maximal amplitude. The two main advantages of this technique is that it provides an efficient rejection of the noise in the acquisition window, and gives a good resolution on the measured time. Nevertheless, the possible influence of the chosen value for the f parameter on this time resolution has to be investigated. We perform such a study in Sec. ???. We concluded that the highest precision on the time measurement arises for $f = 40\%$, and we adopt this value for the following analysis. A graphic representation of the CFD time search is given in fig. 7.3.

As we want to measure the installed cable lengths l_j^m , and compare them to the initially designed ones, l_j^d , we define the length difference ΔL_j as:

$$\Delta L_j = l_j^m - l_j^d. \quad (7.3)$$

On Fig. 7.4 is displayed the distribution ΔL for all the measured lengths. In hypothetical perfect conditions, all the cables should fit the design length, in other words, $l_j^d = l_j^m$. Consequently the ΔL distribution should a peak at zero, as materialised by the black

Figure 7.4: The distribution of difference between the measured lengths l^m and the expected lengths l^d is displayed in orange plain line. The black dashed line represents the case where $l_j^m = l_j^d \forall j$. The Gaussian fit (green dashed line) presents a mean of 10.9 ± 0.3 cm. Some data points considered as outliers are beyond 3σ .

dashed line. However, in real conditions, the measured length can be different from the designed one, leading the ΔL distribution plotted in orange plain line. We conclude that the observed cable length l^m differs from l^d by $+10.9 \pm 0.3$ cm, meaning that cables are longer than expected in average. This may reveal a bias coming from the device used to cut the cables. In fact, during cable cutting work, we noticed that the cutting device had a tendency to slip, probably leading to cables with extra lengths. We assumed the cutting device has a given probability to slip for one meter of cable. If this is the case, the probability for the device to give extra length should increase with the cable length.

To verify this assumption, we plot on Fig. 7.5 the length difference ΔL as a function of the initial design length l^d (cyan). From those data points, we compute a linear fit (orange plain line), parameterised as $y = \alpha x + \beta$, revealing that the cutting device presents two different biases. The value of β shows that the cutting device systematically took away 4.1 cm of each cable. Nevertheless, as the shortest cable was designed to be 10 meters long, there are no important consequences of this bias on the length difference ΔL . Besides, the slope $\alpha = 0.011 \pm 0.002$ of the linear fit reveals that the cutting device adds one centimetre for every meter of cable, being compatible with the hypothesis on the cutting device sliding. Hopefully this bias is not problematic as it makes most of the actual cable lengths longer than the design, while shorter lengths could have lead to systematic connection issues to PMTs. However, we notice that a few cables have been cut too short by

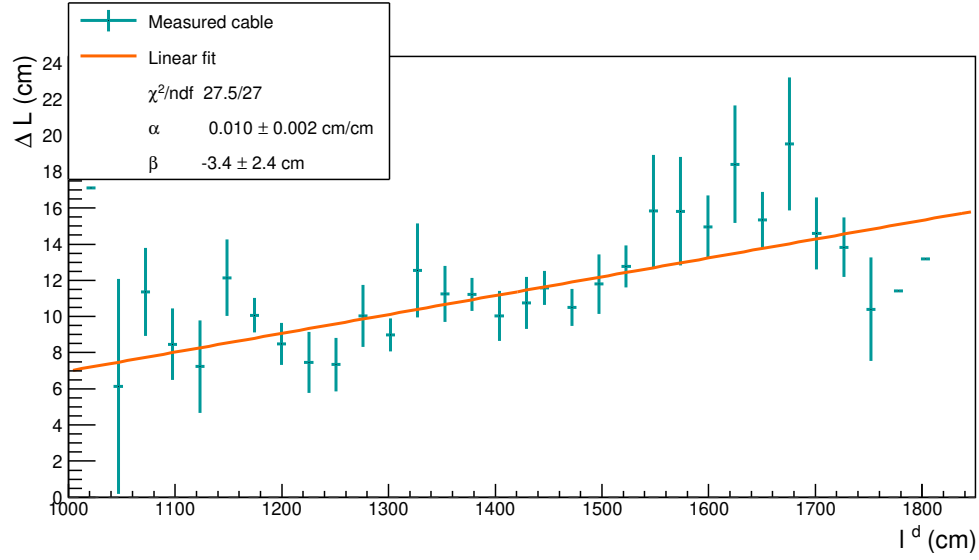

Figure 7.5: ΔL is plotted with l^d (cyan), where l^d is averaged for all the lengths designed to have the same value, being at the origin of vertical error bars. In black dashed line is represented the case where $l^m = l^m$. Data points are fitted by $\alpha x + \beta$, with $\alpha > 0$ and $\beta < 0$, revealing the two biases of the cutting device.

mistake, the worse of them being 80 centimetres shorter than expected. Fortunately, this cable was successfully connected to PMT despite this deficit. On the contrary, few cables have a large extra length. This probably is due to human punctual mistakes on top of the observed bias, but without any strong consequences for the calorimeter operation. In conclusion, no important mistakes have been made when cutting cables, and we had no issue for connecting the only problematic cable.

This study allowed us to control and record the lengths of all coaxial cables installed on the SuperNEMO demonstrator at LSM. We also have understood the main results on measured cable lengths and the functioning of the cutting device that we used.

This work achieved, we want to verify if no cable was damaged after installation. Reflectometry also aimed at checking cable conditions by performing waveform shape analysis on secondary pulses.

7.1.3 Correction on event times

a bouger dans partie cable lengths

The main goal of this study was to check the lengths of coaxial cables. We can also use the results to correct the time of recorded events, taking into account the time for the signal

to travel through cables. This become possible with the reflectometry study we performed. Knowing real lengths of cables and using the celerity of the signal, we deduce the time needed for the signal to travel from one given PMT divider to the electronic boards. Then we can correct event times.

7.1.4 Checking the pulse amplitude attenuation

The attenuation of an electric signal is a problem common to all electronic fields, and comes from the charge loss of an electromagnetic wave travelling in a medium. For a coaxial cable, this attenuation mainly depends on the signal frequency f in MHz and on the cable characteristics. The theoretical linear attenuation $\alpha_{\text{att}}^{\text{th}}$, so be it the attenuation by metre of coaxial cable given in dB/m, is supplied by the constructor as

$$\alpha_{\text{att}}^{\text{th}} = f\sqrt{\epsilon}\left(\frac{a}{\sqrt{f}} + b\right), \quad (7.4)$$

where the factor a depends on the diameter of the dielectric material on one hand, and of the diameter of the conductor material on the other hand, and where b is function of the dielectric loss factor, characterising the material's dissipation of electromagnetic energy. For the used coaxial cables, and with a frequency f of few GHz, this attenuation is valued at $\alpha_{\text{att}}^{\text{th}} = 1.22$ dB/m. In a general manner, the attenuation of a signal in dB is defined a 10 times the decimal logarithm of a power ratio. In the reflectometry analysis, we then define the attenuation \mathcal{A} , for a given length of cable l , as

$$\mathcal{A} = 10 \log_{10} \frac{A_{\text{primary}}}{A_{\text{secondary}}}, \quad (7.5)$$

where A_i is the amplitude of a pulse, defined as the maximum of this pulse. Then, we define the linear attenuation α_{att}^R , measured by reflectometry and given in dB/m, with

$$\mathcal{A} = \alpha_{\text{att}}^R l. \quad (7.6)$$

The goal here is to determine the value of α_{att}^R , using the reflectometry data, and to compare it with $\alpha_{\text{att}}^{\text{th}}$. In Fig. 7.6 is shown the linear dependance between the attenuation \mathcal{A}_R and the cable length l . The fit reveals that the linear attenuation $\alpha_{\text{att}}^R = 0.242 \pm 0.000$ dB/m, that being 5 times smaller that expected with the value of $\alpha_{\text{att}}^{\text{th}}$.
