Sensitivity of the SuperNEMO demonstrator to the $0\nu\beta\beta$

In this chapter, we present a study aiming to evaluate the SuperNEMO's sensitivity to the $0\nu\beta\beta$ decay, and the corresponding effective neutrino mass. Studies of this kind have already been conducted, and the final detector, based on the NEMO-3 technology, is expected to exclude half-lives up to 1.2×10^{26} y (90% CL), with an exposure of 500 kg.y for the $^{82}\text{Se}^{1}$ [8]. In order to assess the feasibility of such a large-scale detector, the SuperNEMO demonstrator started to be installed in early 2015, at the Laboratoire Souterrain de Modane. With an exposure of 17.5 kg.y, this demonstrator could reach a sensitivity on the $0\nu\beta\beta$ process of ^{82}Se 5.3 × 10^{24} y (90% CL) [9].

A copper coil was designed to deliver a uniform 25 Gauss magnetic field inside the wire chamber, to bend the charged particles trajectories, thus making it possible to discriminate between electrons and positrons. However, studies lead by the collaboration determined that this field could be impacted by the detector material (especially by the calorimeter magnetic shields), leading to strong variations in intensity and a loss of energy resolution [9][18]. We aim to explore the impact, on both the demonstrator and final detector sensitivity, of the presence of this magnetic field. The findings of this study will participate in the final decision on the installation of the coil. In a context of investigating the demonstrator and final detector's capabilities, different internal source contamination levels are considered. The topology of interest is the two electrons topology, and we use the total energy sum to discriminate the signal from the background events. Thanks to SuperNEMO tracking capabilities, topological informations are exploited to improve the sensitivity. To go further, we also explore the possibility of studying the $0\nu\beta\beta$ decay of other $\beta\beta$ isotopes.

7.1 The $0\nu\beta\beta$ signal and background model

A full simulation for the demonstrator was performed, in order to determine the upper limit on $0\nu\beta\beta$ half-life that can be probed with SuperNEMO. This sensitivity

¹Supposing the $0\nu\beta\beta$ decay of ⁸²Se occurs through the exchange of a light Majorana neutrino.

depends on the number of selected background events.

Due to the time it would take to simulate every expected background contribution, the choice of a simplified background model, containing only the most harmful backgrounds to the $0\nu\beta\beta$ decay search, was adopted. backgrounds are the $2\nu\beta\beta$ decay, contaminations of the source in ²⁰⁸Tl and ²¹⁴Bi, and contamination of the tracker gas with Radon. The number of natural isotope decay events expected depends on their activities inside the source foils (for ²⁰⁸Tl and ²¹⁴Bi), or on the tracker's wires (for ²²²Rn decaying in ²¹⁴Bi). It was necessary, during the design of the detector, to constrain the maximal tolerable activities, to guarantee a high sensitivity to the $0\nu\beta\beta$ disintegration [10]. collaboration then established recommendations for maximum levels of internal background, given in number of disintegrations per second, for a unit mass of $\beta\beta$ isotope, or for a unit volume of gas. These are the so-called specified activities. The amount of expected double β decays is driven by its half-life value: the higher the half-life, the lower its contribution in the total number of expected background. For ⁸²Se sources, we take the $2\nu\beta\beta$ half-life measured by NEMO-3, $T_{1/2}^{2\nu} = 9.39 \pm 0.17 \text{ (stat)} \pm 0.58 \text{ (syst)} \times 10^{19} \text{ years [11]}$. Moreover, we choose to consider the best limit set on the $0\nu\beta\beta$ process, of $T_{1/2}^{0\nu} > 2.5 \times 10^{23}$ y [11]. This value is given for illustration purposes only and is not used to estimate the sensitivity of the detector. In the Tab. 7.1 is summarised the expected number of signal and background events, per disintegration unit per second, for one kg of source material, or for one m³ of gas inside the tracker. These figures are presented

Process	Expected decays		Simulated decays
	Demonstrator	Final detector	
$0\nu\beta\beta \ (T_{1/2}^{0\nu} = 2.5 \times 10^{23} \ \text{y})$	3.6×10^{2}	1.0×10^{4}	1.0×10^{7}
$2\nu\beta\beta \ (T_{1/2}^{2\nu} = 9.39 \times 10^{19} \ \text{y})$	9.5×10^{5}	2.7×10^{7}	1.0×10^{7}
2^{208} Tl $(\mathcal{A}^{\text{Tl}} = 2 \mu \text{Bq/kg})$	1.1×10^{3}	3.1×10^{4}	1.0×10^{7}
214 Bi $(A^{Bi} = 10 \ \mu Bq/kg)$	5.5×10^{3}	1.6×10^{5}	1.0×10^{7}
$\mathcal{A}^{Rn} = 0.15 \text{ mBq/m}^3$	1.8×10^{5}	7.2×10^{6}	1.0×10^{8}

Table 7.1: Expected and simulated decays for different processes, both for the demonstrator (17.5 kg.y) and for the final detector exposures (500 kg.y), assuming target background activities are reached: $\mathcal{A}^{\rm Tl}=10\,\mu{\rm Bq/kg}, \mathcal{A}^{\rm Bi}=2\,\mu{\rm Bq/kg}, \mathcal{A}^{\rm Rn}=0.15~{\rm mBq/m^3}.$ The measured half-life $T_{1/2}^{2\nu}=9.39\times10^{19}~{\rm y}$ for $^{82}{\rm Se's}~2\nu\beta\beta$ is taken, and we assume $T_{1/2}^{0\nu}=2.5\times10^{23}~{\rm y}$ [11].

both for the SuperNEMO demonstrator and final detector. They represent the total number of disintegrations, without taking into account any technique to reject background, and for the total energy window. Nevertheless, the number of decays presented in this table are expected to be extremely reduced, notably by the application of event selections aimed at maximising the sensitivity to the excluded $0\nu\beta\beta$ half-life (Sec. 7.2). This effect is augmented by the fact that, for the current sensitivity analysis, we focus on a narrow energy window, called region of interest, whose usefulness is described in more detail in Sec. 7.2. Therefore, to properly conduct this sensitivity study, it was necessary to simulate a large

number of events, so that the signal and backgrounds are correctly represented in the region of interest. In the table are presented the total amount of simulated events for each process.

7.1.1 The $0\nu\beta\beta$ signal

The SuperNEMO detector was designed to search for the never-observed $0\nu\beta\beta$ decay. In the following, we assume the underlying mechanism for this decay is the exchange of a light Majorana neutrino, the so-called mass mechanism (MM), as it is the most widespread mechanism. The hypothetical $0\nu\beta\beta$ signal would be detected as an excess of events in the region of interest, with respect to the predicted background contamination levels. Some $10^7 \ 0\nu\beta\beta$ events were simulated inside the source foils, using the DECAY0 software [12].

7.1.2 Inside detector backgrounds

In addition with the $0\nu\beta\beta$ decay, we simulated different types of backgrounds, that could mimic the searched signal.

7.1.2.1 Internal backgrounds

The so-called *internal backgrounds* stand for decays occurring inside the source foils, presenting the same signature as the $0\nu\beta\beta$ signal. These backgrounds, already introduced earlier, are the $2\nu\beta\beta$ of the source isotope, as well as disintegrations of ²⁰⁸Tl and ²¹⁴Bi inside the source foils.

The $2\nu\beta\beta$ process

In the full energy range, the allowed $2\nu\beta\beta$ decay stands as the dominant internal background type. Its total energy spectrum is a continuum, whose ending point should stands at $Q_{\beta\beta}=2.99$ MeV, but is slightly shifted by the detector's energy resolution. We simulated 10^7 events of this decay inside the source foils, in the full energy window. However, above a certain energy value, the number of $2\nu\beta\beta$ events decreases very quickly. To offset this effect, we simulated additional 10^7 of this decay on a slightly reduced energy range, that is to say above 2 MeV. The second set of simulations is normalised with the first one. In this way, the lack of $2\nu\beta\beta$ simulated events in the high-energy tail is avoided, without requiring too high computational resources.

Source foils contamination by natural isotopes

As described in Sec. 3.2.1, after sources purification, remaining natural isotopes such as 208 Tl or 214 Bi can still be present inside the foils, constituting the principal internal source of background, with the $2\nu\beta\beta$ decay. We simulated 10^7 decays both for the two isotopes, inside the source foils.

7.1.2.2 Tracker contamination by natural isotopes

The presence of gaseous ²²²Rn inside the tracker, mainly deposited on the copper wires, can produce events similar to internal one. In fact, one of the progeny of ²²²Rn, the ²¹⁴Bi, can decay on (or near) a foil, and appear with a two-electron (2e) topology, becoming hard to distinguish from a double beta decay candidate. As this isotope is distributed throughout the whole tracking detection volume, to study the experiment's sensitivity, we simulated a large quantity of this decay, that is to say 10⁸ decays on the tracker wires.

7.1.3 External backgrounds

This background category is populated by the external γ -ray flux produced by radioactive isotope decays in detector components or surrounding laboratory rocks, as well as neutron interactions in the external iron shield. As external background simulations would be very consuming in terms of computing ressources, it is important to ensure that they are necessary. The NEMO-3 experiment set a limit on the external background number of counts, of < 0.2 events in the 2e topology, for the energy range [2.8;3.2] MeV (two electrons energy sum), for an exposure of 34.3 kg·y, with ¹⁰⁰Mo sources [13]. Radiopurity measurements of the SuperNEMO PMTs allow to conclude that the total ²¹⁴Bi activity is 35% better than for those of NEMO-3 [14], which is encouraging. Unfortunately, these measurements also revealed that the total budget in ²⁰⁸Tl isotope is 150% higher than NEMO-3. This could lead us to think that the external background for SuperNEMO could be higher than that of NEMO-3. However, on that level, the most notorious difference between the two detectors is the fact that the SuperNEMO scintillator blocks are thicker than those of NEMO-3. Therefore, a gamma is more likely to be detected before crossing the source foils and, in that case, the event would not contribute to the background in the 2e channel. Even if the regions of interest are slightly different between these two experiments, it produces negligible increase on the external background contribution². After all, given the fact that SuperNEMO is expected to be better than NEMO-3 at rejecting external background events, we consider that all external backgrounds from outside the foil, apart from ²²²Rn in the tracking volume, are expected to be negligible, and were not simulated.

7.2 Event selection

For SuperNEMO, the $0\nu\beta\beta$ signature is two-electrons events, emitted simultaneously from the same vertex on the source foils, with an energy sum compatible with $Q_{\beta\beta}=2.99$ MeV for the ⁸²Se. Therefore, we conducted this analysis selecting only events matching the 2e topology, where a reconstructed particle is tagged as an electron if it has

²A study conducted by the SuperNEMO collaboration shown that only 0.73 additional external background events would have been expected for the NEMO-3 detector, if instead of taking the [2.8;3.2] MeV energy range, we would have considered the [2.7;3.15] MeV region of interest.

- a vertex on the source foils,
- a reconstructed track inside the wire chamber,
- an associated calorimeter hit,
- and a final criterion depending on the case under consideration. In fact, as announced, this study also aims at considering two separate magnetic field cases. One where the magnetic field is aligned with the Z (vertical) axis of the detector, and has a uniform value of 25 Gauss, and one where the field is turned off. In the first case, particles such as electrons and positrons of a few MeV have a curved trajectory in the tracker. In the second case, the tracks of the particles may be similar to straight lines (not to mention the possible multiple scattering on the wires of the tracker). It is then necessary to adapt the selection of events to each case. We then consider an additional criterion: a particle is identified as an electron if its track has a negative curvature. In the following, we present results where the magnetic field is turned on. The off-field study is addressed in Sec. 7.5.

All these selections represent the so-called *first-order* cut-offs. We present the total energy spectra for each simulated process, after application of these cut-offs, in Fig. 7.1. We present results for the specific case were of the demonstrator (82 Se sources, 17.5 kg.y exposure), with the specified internal contamination levels ($\mathcal{A}^{Tl} = 2 \mu Bq/kg$ and $\mathcal{A}^{Bi} = 10 \mu Bq/kg$).

If the $0\nu\beta\beta$ decay is detected, its energy distribution would be a peak, located at the end-point of the $2\nu\beta\beta$ energy distribution, that is to say at the total available energy, $Q_{\beta\beta} = 2.99$ MeV. In principle, this peak is infinitly thin, as the two electrons of this decay would share the total available energy. However, the two emitted electrons may lose some of their energy in the detector, mainly inside the dense source material and the wire chamber, which would lead to the widening of this peak. It is also expected to be shifted towards small energies, by the calorimeter energy resolution and the straggling of energy losses in the detector. All this is at the origin of the asymmetrical energy distribution shown in the figure. Concerning the $2\nu\beta\beta$ energy spectrum, we only present the events simulated with an energy > 2 MeV, even if all simulated events were taken into account for this study. Whatever their origin, either ²²²Rn contaminations inside the tracker gas, or internal contaminations of the source foils, the two ²¹⁴Bi energy distributions have nearly the same shapes. The ²⁰⁸Tl spectrum reveals the internal conversion of the 2.614 MeV gamma, emitted after 208 Tl β^- disintegrations. All spectra are normalised to the natural isotopes specified activities, and the half-lifes values.

A widespread technique consists in constraining the $0\nu\beta\beta$ decay searches to a narrow energy range, the so-called region of interest (ROI), materialised by the two vertical dashed lines in the figure. In the following, we expose general principles leading to the determination of the best limit on $T_{1/2}^{0\nu}$, in the appropriate region of interest. We illustrate the reasoning with the demonstrator, specified activities, on-magnetic field case. However, the technique presented remain valid for all exposures, internal contamination levels and field conditions. The impact of all these parameters is detailed in the rest of the chapter.

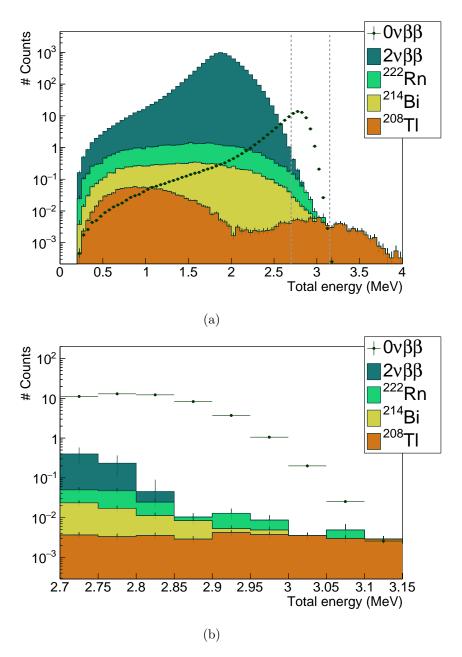

Figure 7.1: Total energy spectra for the $0\nu\beta\beta$ signal and main backgrounds, for (a) the full energy range, and (b) for the [2.7;3.15] MeV energy range, whose optimisation is discussed in Sec. 7.3.

7.3 Demonstrator sensitivity to the 82 Se $0\nu\beta\beta$ decay

In case of the non-observation of a $0\nu\beta\beta$ signal, the expected upper limit on the half-life is provided for a given $[E_{\min}; E_{\max}]$ energy range, and depends on the characteristics of the detector. First, it depends on the signal detection efficiency $\epsilon_{0\nu}$ in this energy window, secondly on the source isotope nature, as well as the

detector's exposure $m \times t$. It follows

$$T_{1/2}^{0\nu} > \frac{\mathcal{N}_{A} \ln 2}{M} \times \frac{\epsilon_{0\nu} \times m \times t}{N_{0\nu}^{\text{excl.}}}, \qquad (7.1)$$

with \mathcal{N}_{A} the Avogadro number, m the quantity of isotope in the source foils, M its molar mass, and t the total time of data taking. $N_{0\nu}^{\rm excl.}$ is the number of signal events excluded, calculated with the Feldman-Cousins statistics from the total expected number of background events. The Feldman-Cousins statistics [15] is a wide-used method in rare events search experiments, providing confidence intervals for upper limits in the case of Poisson processes with background. We use this method in the framework of this analysis to provide a limit, at 90% CL, on the number of expected signal events $N_{0\nu}^{\rm excl.}$, on the basis of the expected number of background events, given below.

• The $2\nu\beta\beta$ background

In Eq. (7.1), we defined the upper limit on $T_{1/2}^{0\nu}$ from the number of excluded signal events, and the signal selection efficiency $\epsilon_{0\nu}$. The same way, we can define the number of expected $2\nu\beta\beta$ events, $N_{2\nu}$, from the half-life $T_{1/2}^{2\nu}$ and the $2\nu\beta\beta$ selection efficiency, $\epsilon_{2\nu}$, as

$$N_{2\nu} = \frac{\mathcal{N}_{A} \ln 2}{M} \times \frac{\epsilon_{2\nu} \times m \times t}{T_{1/2}^{2\nu}}.$$
 (7.2)

• Natural radioactive backgrounds

We consider the background massic activities $A_{\rm rad.}$, and $\epsilon_{\rm rad.}$ their selection efficiencies in a given energy window. The number of background events is therefore given, for the $^{208}{\rm Tl}$ and $^{214}{\rm Bi}$ internal contaminations, as

$$N_{\rm rad.} = A_{\rm rad.} \epsilon_{\rm rad.} \times m \times t \tag{7.3}$$

where $A_{\rm rad}$ is given in Bq/kg. Similarly, for the ²²²Rn background,

$$N_{\rm rad.} = A_{\rm rad.} \epsilon_{\rm rad.} \times V \times t$$
, (7.4)

with $V = 15.3 \text{ m}^3$ the tracker volume, and where $A_{\text{rad.}}$ represents this time a volumic activity, given in Bq/m³.

All these equations, similarly as Eq. (7.1), are valid for a given energy range $[E_{\min}; E_{\max}]$. To find the optimal energy interval for the search of the $0\nu\beta\beta$ decay, that is to say the one maximising the limit on $T_{1/2}^{0\nu}$, we must vary the E_{\min} and E_{\max} bounds.

As can be seen in Fig. 7.1, beyond a certain value in energy, the number of background events becomes negligible. Indeed, the ²⁰⁸Tl background dominates at these energies, where it does not exceed one count for E> 3.2 MeV. This is why the upper limit E_{max} of the energy interval has only a limited impact on the search for the best ROI. It is then natural to study mainly the influence of the lower limit E_{min} . Therefore, the selection efficiencies, entering in the calculation of the $T_{1/2}^{0\nu}$ upper limit, are presented in Fig. 7.2, as a function of $E > E_{\text{min}}$. We remind a

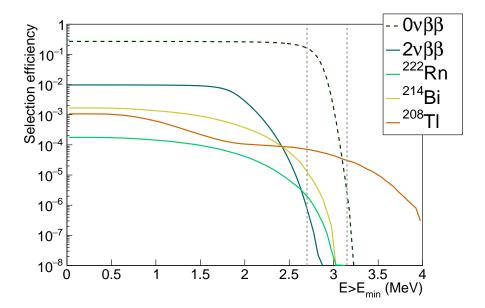

Figure 7.2: Efficiency spectra as a function of $E > E_{min}$, for the $0\nu\beta\beta$ signal (dashed black line) and for the main backgrounds (plain lines). The two vertical grey lines represent the final ROI optimised for the case of the demonstrator, taken the specified isotope activities.

selection efficiency ϵ is the ratio of the number of selected events, to the number of simulated events. As a matter of fact, we look for an energy region where $\epsilon_{0\nu}$ is high, and where selection efficiencies for the background are low. This choice directly determines the best value for $T_{1/2}^{0\nu}$ (90% CL), whose variation as a function of E_{\min} and E_{\max} are presented in Fig. 7.3. As we said, the energy range chosen as the region of interest for the search of the $0\nu\beta\beta$ decays is the one maximising the $T_{1/2}^{0\nu}$. We found that, for the demonstrator exposure, with ⁸²Se sources, with a 25 G magnetic field, and for the specified background activities, the best ROI is [2.7;3.15] MeV. In this optimised energy range, the sensitivity expected for the SuperNEMO demonstrator stands at

$$T_{1/2}^{0\nu} > 5.7 \times 10^{24} \,\mathrm{y}$$
 (90%CL). (7.5)

This result is compatible with the previous analysis lead by Steven Calvez [9].

In this section, we presented the general procedure leading to an optimised result on the $T_{1/2}^{0\nu}$ limit, and we gave the best limit on $T_{1/2}^{0\nu}$, driven by Eq. (7.1), for the demonstrator case. Thereafter, we discuss the results obtained for different detector exposures (demonstrator and final detector), and different internal background activities. Also, and this is the main purpose of this study, we discuss the influence of the presence of the magnetic field on the final detector's sensitivity.

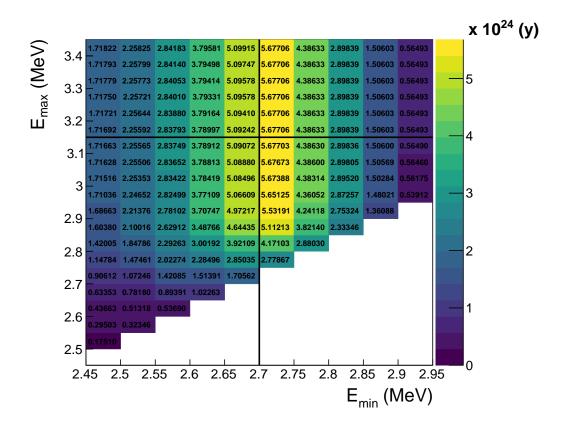

Figure 7.3: Two-dimensional histogram showing the evolution of the $T_{1/2}^{0\nu}$ value as a function of the lower and upper energy bounds. The maximal upper limit of $T_{1/2}^{0\nu} > 5.7 \times~10^{24}~\mathrm{y}$ (90% CL) is retained, in the [2.7;3.15] MeV region of interest.

7.4 Impact of sources contamination levels on the sensitivity

We study the impact of the isotope contamination levels (inside the source foils, as well as on the tracker's wires) on the $0\nu\beta\beta$ sensitivity. We also optimise additional event selections aimed at improving the final sensitivity result.

7.4.1 Influence of the contamination levels

Specified contamination levels have been established in order to achieve the $0\nu\beta\beta$ half-life target of $\sim 1 \times 10^{26}$ years for the final detector. The ⁸²Se demonstrator source is segmented in 34 foils, whose production was the responsibility of different laboratories (Dubna, LAPP and Tomsk). The sources have undergone different purification treatments, in order to investigate new techniques, and to compare them with those of NEMO-3. After the sources production and purification, preliminary measurements have been performed with the BiPo-3 detector to determine the actual ²⁰⁸Tl and ²¹⁴Bi contamination levels inside the foils [16]. The level of radon emissions inside the tracker was also measured by the collaboration, for each of the four sections of the chamber, using a concentration line. We

summarise all these contamination levels in Tab. 7.2, and give a comparison with the detector initial specifications. The targeted ²⁰⁸Tl level is not reached,

	Specified activities	Measured activities
²⁰⁸ Tl	$2\mu\mathrm{Bq.kg^{-1}}$	$54 \mu \mathrm{Bq.kg^{-1}}$
²¹⁴ Bi	$10 \mu {\rm Bq.kg^{-1}}$	$< 290 \mu {\rm Bq.kg^{-1}}$
222 Rn	0.15 mBq.m^{-3}	$0.15 \pm 0.02 \text{ mBq.m}^{-3}$

Table 7.2: Real and targeted specified activities for the SuperNEMO detector. The 222 Rn tracker contamination is measured with a concentration line [17], extrapolated with a 2 m³/h flow rate. The limit on 214 Bi contamination is provided by BiPo measurements for a 90% CL [16].

being almost 27 times higher than expected, and 3.0×10^4 internal Thallium events are expected in 2.5 years. Nevertheless, in average, a factor of two was gained between the NEMO-3 100 Mo sources and the 82 Se sources from the demonstrator. In addition, valuable information has been accumulated on the different production techniques, which are of great importance for the final detector construction. In particular, the two best 208 Tl sources activities were reached by inverse chromatography, reaching a $20\pm10~\mu\mathrm{Bq/kg}$ level, an improvement by a factor 5 compared to NEMO-3. This encourages for further investigations in this direction. The sensitivity of BiPo detector only allowed to give an upper limit on the level of internal $^{214}\mathrm{Bi}(\mathrm{an}$ activity of 290 $\mu\mathrm{Bq/kg}$ would correspond to 1.6×10^5 internal Bismuth events in 2.5 years). Precise measurements are expected from the demonstrator calibration. Radon emissions from the tracker were also measured, and extrapolated with an air flow rate of 2 m³/h inside the chamber, showing the targeted level of 0.15 mBq.m $^{-3}$ was reached.

In Sec. 7.3, we developed the general procedure allowing to set a 90% confidence interval limit on $T_{1/2}^{0\nu}$. For the demonstrator, supposing the specified activities are reached, the demonstrator would achieve a sensitivity of 5.7×10^{24} years on the searched decay, in 2.5 years of data taking, with 7 kg of ⁸²Se. This sensitivity could be affected by the higher-than-expected level of contaminations, measured by BiPo, inside the source foils. We expose in Fig. 7.4 the $T_{1/2}^{0\nu}$ limit as a function of the contamination levels, as well as the corresponding chosen region of interest. Four distinct levels of internal contaminations are considered:

- the zero activities case, a hypothetical case where the source foils and the tracker are non contaminated at all.
- the *specified activities* case, were the targeted level of contaminations would have been reached,
- and two measured cases, that take into account the measured levels of contaminations at 90% CL. As the 214 Bi activity is provided by BiPo measurements as an upper limit, it is possible for this level to be lower than $290 \,\mu\text{Bq/kg}$. We therefore present the results, either for sources that would not be contaminated by this isotope (the without 214 Bi case), or considering that the activity reached is $290 \,\mu\text{Bq/kg}$ (with 214 Bi).

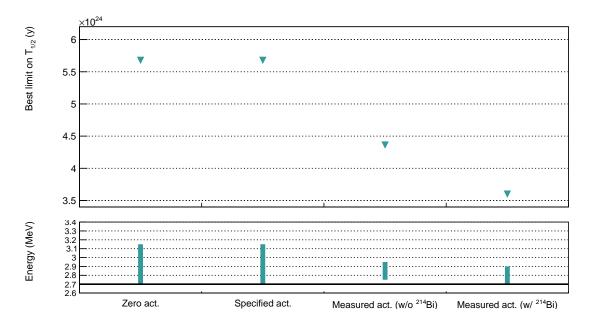

Figure 7.4: The 90% CL limit on the $0\nu\beta\beta$ half-life (top pad), and the corresponding ROI (bottom pad), as a function of the contamination level considered. For the zero activities case, we consider hypothetical contamination levels where $\mathcal{A}^{\rm Bi} = \mathcal{A}^{\rm TI} = 0$ Bq/kg. The specified activities are presented in Tab. 7.2. The measured activities, provided by the BiPo detector [16], are presented in the same table. We consider successively a null ²¹⁴Bi contamination (measured act. w/o ²¹⁴Bi), or equals to the 290μ Bq/kg upper limit (measured act. w/ ²¹⁴Bi).

The fact that we are showing results for a hypothetical zero isotope contamination is to illustrate an important statistical phenomenon. Indeed, we notice that there is no difference in sensitivity, or ROI, between the first two cases of contamination, which may seem surprising at first glance. This is explained by the Feldman-Cousins statistics employed to determine the number of excluded signal events, $N_{0\nu}^{\rm excl.}$, given the number of observed background events (defined from Eq. (7.2) to Eq. (7.4)). When the expected number of background events is negligible (which is the case for the two first levels presented), the probability p to observe n_s signal events, expecting s events, is given by the Poisson distribution

$$p = \frac{e^{-s}s^{n_s}}{n_{c!}}. (7.6)$$

Let's now put ourselves in the situation where no signal event is observed - that is what we assume to put an upper limit on the $0\nu\beta\beta$ half-life. Then $n_s \to 0$, and $p \to e^{-s}$. If zero signal event is observed, it is uncorrect to assume that zero signal events were produced during the experiment. We only can say that no signal event has been observed a priori. As a consequence, the quantity s is no longer the number of expected signal events, but is the number of excluded signal events, $N_{0\nu}^{\rm excl.}$. In the end, for a negligible expected number of background events, and no signal event observed, we can set an upper limit on the number of excluded signal events, excluding values for which $p < \alpha$. Taking a 90% confidence interval, that is to say $\alpha = 10\%$, we obtain $s \le 2.303$. A direct consequence of this statement

is, considering that the background levels for the two first cases are negligible (or null) in the region of interest, they both reach this limit of 2.303 on the excluded number of signal events. Therefore, due to the Feldman-Cousins statistics, no difference is observed in terms of half-life limits between these two contamination cases.

When considering the measured internal activities, a decrease in sensitivity is observed, compared with the specified activities case. Indeed, the number of background events in the ROI is no more negligible, and influence significantly the value of $T_{1/2}^{0\nu}$, decreasing the experiment's sensitivity by 23% (without ²¹⁴Bi) and 37% (with ²¹⁴Bi). Both region of interests are also highly reduced, especially for the third contamination case, where the lower bound is greater than 2.7 MeV, an energy region populated with a non-negligible number of background events. This impacts significantly the signal-to-background ratio, and as addressed in the next subsection 7.4.2.

The degradation of the limit with the level of contamination remains acceptable. However, we can try to improve the situation by exploring new event selection techniques, with the aim of maximising the limit on $0\nu\beta\beta$ half-life.

• préciser que si ça se trouves les niveaux de cont. sont plus élevés que ça, car pas toutes les sources ont été mesurées, et que certaines valeurs sont des limites sup.

7.4.2 Optimisation of the event selection

The measured level of ²⁰⁸Tl isotope inside the source foils is greater than the specifications Moreover, an upper limit, higher than the specified level for SuperNEMO, has been set by the BiPo detector, regarding the internal ²¹⁴Bi level. Consequently, we can imagine implementing stricter cut-offs, to reject a background level higher than the specifications. Most of the double beta experiments are only sensitive to the total electron energy sum. The unique SuperNEMO tracko-calo technology confers the experiment the ability to characterise single particles (individual energies, emission angles...). By relying on these additional observables, topological cuts have been set up. They are especially designed to reject events where the two electrons are not emitted simultaneously, or from the same location on the source foils.

The internal probability Based on time-of-flight (TOF) computation, the internal probability (P_{int}) is derived from the internal χ^2 (see details in Sec. 4.1.1). In Fig. 7.5 are presented the internal probability spectra for the $0\nu\beta\beta$ signal and all background processes, after the first-order selections. These distributions are normalised to the double beta half-lives, and the nominal activities. Equivalent distributions, but with different ²¹⁴Bi and ²⁰⁸Tl contamination levels, can be derived for the case of measured activities. The internal probability distributions for the $0\nu\beta\beta$ and $2\nu\beta\beta$ processes follow the expected flat distribution for electrons emitted simultaneously from the source. As the disintegration of Bismuth actually takes place from the sources, the ²¹⁴Bi distribution is also flat. The same could

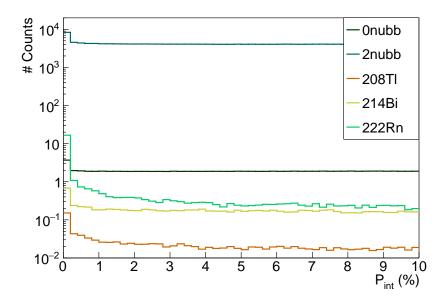

Figure 7.5: Internal probabilities for all processes. First-order cuts have been applied. $\beta\beta$ distributions are normalised to the half-lives, and background processes are normalised to the specified activities.

have been assumed for Thallium, however, the distribution is distorted at low internal probabilities. This might be explained by the existence of a metastable excited state ($\tau_{1/2} = 294ps$) of the daughter nuclei, which would slightly delay the second electron emitted via internal conversion. This feature is addressed in detail in Chap. 8. The Radon, being a non-internal background, presents a peak at low internal probabilities.

We want to evaluate the influence of a cut-off on the simulations using internal probability as a rejection criterion: simulated events are selected for P_{int} values upper than a given limit. The standard value applied in NEMO-3 analyses was $P_{int} > 4 \%$. We wish to establish the most adequate P_{int} selection level for the SuperNEMO demonstrator. For each internal probability cut-off applied to the simulations, we evaluate the $T_{1/2}^{0\nu}$ at a 90 % confidence interval, as well as the best ROI. The internal probability value that will be chosen will be the one that maximises the sensitivity, and depends on the internal level of contamination. To better understand this optimisation, let us present the $\epsilon_{0\nu}$ values for each $P_{\rm int}$ selection case, in Fig. 7.6a, both for the specified and measured contamination levels. For the latter, we assume the Bismuth upper limit of 290 μ Bq/kg activity is reached. As expected, in both cases, the $\epsilon_{0\nu}$ selection efficiency globally decreases with the P_{int} cut-off applied. However, for the measured contamination case, we observe a slight increase of the $0\nu\beta\beta$ selection efficiency, for $P_{\rm int} > 1 \%$. Fig. 7.6b, showing the variations of the regions of interest as a function of the P_{int} rejection criterion, allow to understand this observation. For the measured activities case, from the level $P_{int} > 0 \%$ to $P_{int} > 1 \%$, the ROI upper bound increases from 2.9 to 3.05 MeV. Usually, the variation of this bound does not have such a great impact on the event selection. Nevertheless, in the measured activities case, for a $P_{int} > 0$ % level, the ROI is optimised at the narrow [2.7;2.9] MeV interval,

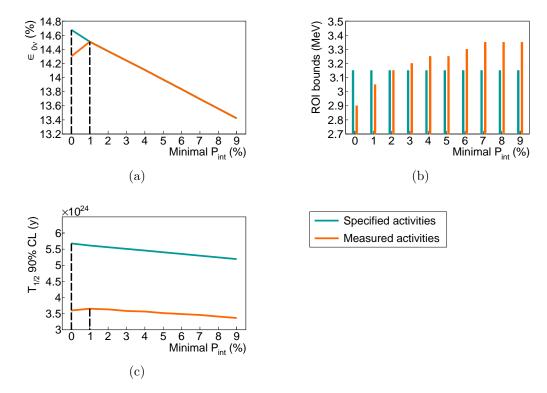

Figure 7.6: $0\nu\beta\beta$ selection efficiency (a), evolution of the region of interests (b), and best limits set on $T_{1/2}^{0\nu}$ at 90% CL, as a function of the cut-off applied on internal probability. Results are displayed for two contamination levels: the specified (blue) and the measured (orange) activities. An exposure of 17.5 kg.y is considered. Two vertical dashed lines in (a) and (c) display the best $P_{\rm int}$ selections to be applied in order to improve the $T_{1/2}^{0\nu}$ sensitivity of the experiment.

where the upper bound is located in an energy region still populated by signal and bakground (see Fig. 7.4). Therefore, even small variations in this ROI has a great impact on the results, explaining the local increase in efficiency. For P_{int} selections greater than 1 %, we come back in cases where the upper limit of the ROI no longer has an impact on $\epsilon_{0\nu}$. For the specified ativities case, the ROI bounds are stable, not impacting the selection efficiency.

As the limit set on $T_{1/2}^{0\nu}$ depends directly on $\epsilon_{0\nu}$, the variations presented in Fig. 7.6a fully explain the results displayed in Fig. 7.6c, presenting the evolution of $T_{1/2}^{0\nu}$ with the internal probability selection level. The sensitivities displayed for a 0% cut-off on $P_{\rm int}$ of course correspond to the results given in Fig. 7.4. The main conclusion is that this rejection criterion has only a limited impact on the improvement of $T_{1/2}^{0\nu}$ sensitivity, because of the very low contamination levels considered. Indeed, paradoxically, the selection on internal probability worth it only if there is enough background events to be rejected. The former 4 % value recommended by the NEMO-3 analysis is then too high for the SuperNEMO source contamination.

For future studies, it is useful to know the efficiencies of selection of this cut-off, for the signal and for each background considered. Those are given in Tab. 7.3, for the first-order cuts and for a > 1% internal probability level. The latter has a huge

Process	First-order cuts (%)	Internal probability (%)
$0\nu\beta\beta$	26.9	26.2
$2\nu\beta\beta$	22.1	21.4
²⁰⁸ Tl	0.106	0.0955
²¹⁴ Bi	0.168	0.158
222 Rn	0.0169	8.99×10^{-3}

Table 7.3: Number of selected 2e topologies compared with the total number of simulated decays, for first-order and P_{int} selections, in the full energy range.

impact on Radon selection, as it is a non-internal background. It is also efficient in rejecting Thallium internal events, because of the existence of a metastable exited state, described earlier.

NEMO-3 analyses also used the distance between the reconstructed vertices on the source foils as a background rejection criterion. As we shown that the additional $P_{\rm int}$ cut-off is poorly adapted for the low activities of SuperNEMO sources, it is interesting to know if we can improve the results by using this second selection.

Vertices distance As discussed in Sec. 7.2, an electron is defined as a reconstructed track inside the wire chamber, with one extremity on a calorimeter block, and another on a source foil. Therefore, the 2e topology involves two distinct calorimeter hits, two reconstructed tracks, and two foil vertices. Thanks to the trajectory fitting algorithm, we have access to the (Y, Z) coordinates of the latter, and by extension, to the distance between them. In the previous studies, the choice was made to look at the effect of this selection, separately on the Y (perpendicular to the wires) and Z (parallel to the wires) directions. We choose to follow the same approach, and we give the results for a cut along the Z axis, but the conclusions remain valid for the Y direction. Fig. 7.7 shows the distributions of the absolute value of the distance between foil vertices for each process studied. We would use this information in order to maximise the double β decays to be selected, while rejecting natural isotope disintegrations.

Fig. 7.8 displays the limit set on $T_{1/2}^{0\nu}$ as a function of this event selection, allowing to study the impact of the vertices distance cut-off on the final sensitivity. In the same way as previous paragraph, we study the influence of the level of contaminations by showing results for the two specified and measured activities. The two distributions reach a plateau, corresponding to the sensitivities achieved with the first-order cuts (Fig. 7.4). Regardless of the level of contamination, the number of background events is too low in the ROI for the $|\Delta Z|$ cut-off to be worthwhile. Therefore, the cut-off only degrades the sensitivity, as does the selection on internal probability. The same conclusions apply to the $|\Delta Y|$ cut-off.

However, such a cut-off could be useful for rejecting unexpected background (where two electrons are emitted from two independent sources, for instance). For example, we note that a cut-off at $|\Delta Z| < 80$ mm does not significantly degrade sensitivity. In practice, a selection on vertex distance will always be applied, even

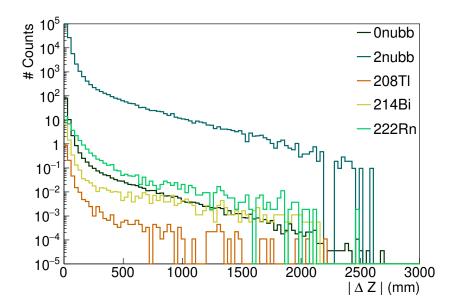

Figure 7.7: Distance between vertices along the Z direction, for each process considered.

if it is very loose.

The idea of having implemented these two selections (on the internal probability and on the distance between vertices) comes from a previous NEMO-3 analysis on the background rejection. However, the levels of contaminations we are dealing with is remarkably low for most of the the topological cut-offs to be worth applying. Finally, we do not apply any cut-off in internal probability, and the cut-off on vertex distance is kept for $|\Delta Z| > 80$ mm. After looking at the effect of contaminations on the sensitivity, we review the influence of the magnetic field inside the detector.

7.5 Impact of the magnetic field on the sensitivity

The SuperNEMO demonstrator was originally designed with a copper coil, similarly to NEMO-3, delivering a magnetic field inside the tracker volume, aiming to provide an electron/positron discrimination. This 25 G magnetic field is high enough to bend the trajectory of the few MeV electrons and positrons of interest for SuperNEMO, without preventing them from reaching the calorimeter. In practice, this magnetic field is mainly used to identify and reject the electron-positron pairs created by high energy γ 's, themselves emitted after a neutron capture. In this study, however, we choose to not consider the contribution of this external background. We therefore focus on evaluating the influence of the presence of the magnetic field on the rejection of internal and wire chamber backgrounds.

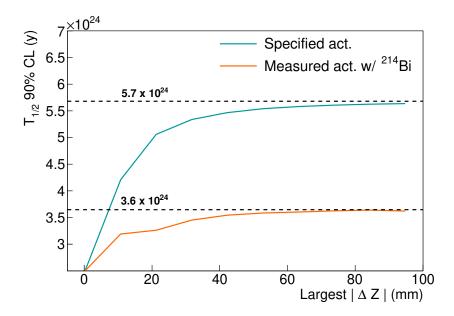

Figure 7.8: Best reached limit on $T_{1/2}^{0\nu}$, as a function of the cut-off applied on the Z distance between vertices. Results are displayed for specified (blue), and measured contaminations (with the 214 Bi contamination (orange) or without it (green)). No improvement in sensitivity is obtained with this event selection.

7.5.1 Simulations of the magnetic field inside the demonstrator and reconstructed track fit

In order to study the influence of the magnetic field on the 82 Se $0\nu\beta\beta$ sensitivity, the simulations and reconstructions of decays described in Sec. 7.1 have been performed in two different conditions.

- Simulations with a 25 G magnetic field (following recommendations [9]). Results about the final sensitivity achieved in this condition have already been presented earlier in this chapter. The possible variations of the field intensity, mainly due to the calorimeter magnetic shields, are not taken into account for these simulations. This will be discussed in subsection 7.5.4.
- Simulations where the magnetic field is turned off.

Each magnetic field condition has the same number of simulated events, as summed up in Tab. 7.1. Depending on the case considered, the electrons do not have the same trajectory curvature. In the first uniform on-field case, the best track fit is performed by helices. In the second off-field case, the trajectory of an electron is modelised by a straight line. The fitting algorithm is thus modified to match line trajectories.

7.5.2 Impact of the magnetic field on signal and background selections

Among the various event selection criteria considered in Sec. 7.2, the last one is of primary importance with regard to the influence of the magnetic field on the final sensitivity of the detector. Indeed, when the magnetic field is switched on, the charged particles of few MeV (as electrons and positrons) have curved trajectories. A particle is then identified as an electron when the trajectory fitting results in a negative curvature. When the magnetic field is switched off, the trajectory of the charged particles takes place in a straight line³. This last selection criterion on the track curvature is then no longer applied. Consequently, the number of identified 2e topologies, selected by the first-order cuts, are increased, for the signal and background simulated events. To illustrate this effect, we give in Fig. 7.9 the selection efficiencies of signal and background as a function of the 2e total energy, for the two cases of magnetic field presented above. The two coloured stripes

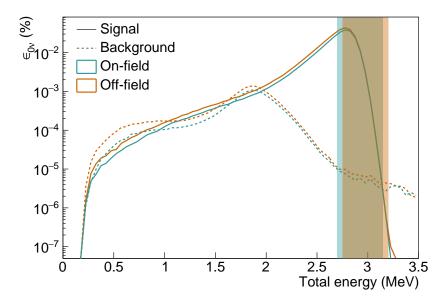

Figure 7.9: The $0\nu\beta\beta$ selection efficiency as a function of the 2e total energy, for the on-field (blue) and the off-field (orange) cases. The two corresponding region of interests are also displayed by coloured stripes. Here no optimised topological cut-offs have been applied.

represent the corresponding region of interests, of [2.7;3.15] MeV for the *on-field* case, and [2.75;3.2] MeV for the *off-field* case. These results are presented for the specified contamination levels, but remain valid in all cases. We clearly notice that, for the total energy interval [0;4] MeV, the number of signal and background selected events is higher in the off-field case, which confirms what we were saying above.

Following Eq. (7.1), the ratio $\epsilon_{0\nu}/N_{0\nu}^{\rm excl.}$ in the ROI impacts the final sensitivity. Nevertheless, as we explained in the previous section, the low contamination level

³In saying this, we do not take into account possible deviations in the trajectory of the particles, due in particular to multiple scattering in the tracker.

considered causes $N_{0\nu}^{\rm excl.}$ to reach the 2.303 limit. Thus, only variations of $\epsilon_{0\nu}$ in the ROI, between on-field and off-field cases, are the source of modifications on the final sensitivity. Integrating $\epsilon_{0\nu}$ over the ROI, we obtain $\epsilon_{0\nu}^{\rm on-field} = 0.15\% > \epsilon_{0\nu}^{\rm off-field} = 0.12\%$. The selection efficiency for the on-field case is favoured by the lower bound of the ROI. In fact, the further this lower bound is shifted towards lower energies, the greater the selection efficiency. Besides, slight variations of the upper bound have almost no impact. As expected, this results in a decrease in sensitivity when the field is switched off, giving

$$T_{1/2}^{0\nu} > 4.80 \times 10^{24} \,\mathrm{y}$$
 (90%CL). (7.7)

However, this decrease in sensitivity can be compensated by applying the topological cut-offs described in subsection 7.4.2. We optimised these selections for each contamination level case, and for both field and no field cases. In Fig. 7.10 are summurised the best values for $T_{1/2}^{0\nu}$, using optimised topological cut-offs, both for on-field (see Sec. 7.4.2) and off-field cases. The common result at all activity

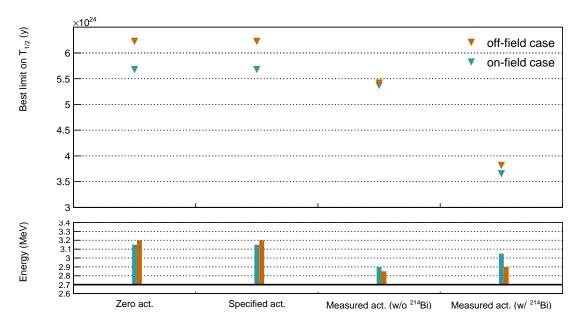

Figure 7.10: Best limit set on $0\nu\beta\beta$ half-life (top pad), and the corresponding ROI (bottom pad), as a function of the contamination level considered, for both on-field and off-field cases.

levels is that the sensitivity is increased for the non-field case when applying the optimised topological selections. For instance, for the specification case, $T_{1/2}^{0\nu}$ goes from 4.80×10^{24} y to 6.22×10^{24} y, an improvement of 30%. This is due to the fact that, in both magnetic field cases, $\epsilon_{0\nu}$ is reduced by the application of these cuts. However, in the case of no field, a greater number of 2e topologies passed the first-order selections. Then, the topological cuts become interesting, and make it possible to reach higher sensitivities. This argument is supported by the fact that, for higher contamination levels (i.e. measured activities with and without bismuth), the difference in sensitivity for the two magnetic field cases tends to decrease.

Finally, even if the application of the magnetic field has the effect of reducing the sensitivity to $0\nu\beta\beta$, topological cuts allow this effect to be compensated for, and make it possible to arrive at comparable values of $T_{1/2}^{0\nu}$ in both magnetic field conditions.

• pour la variation de la ROI dans la figure comparative des différents level en contaminations : la ROI bouge pour les cas measured. C'est étonnant à premièer vue car ça ne paraît pas optimal et ça rajoute du Bi. Mais en fait si on regarde les biplots de sensibilité, on a des fluctuations. Mais ce ne sont pas de grosses fluctuations, ce qui est aussi rassurant car ça veut dire qu'on n'est pas trop sensible aux variations de Emin/Emax (même si j'ai dit qu'on y était pas mal sensible -¿ à regarder)

7.5.3 Influence of the magnetic field on optical modules and reconstruction efficiency

In the previous subsection, a comparative study has been lead to evaluate the influence of the presence of a magnetic field on the event selection, and thus on the final sensitivity. However, as things stand now, some features of the demonstrator are not yet implemented in the simulations, and could have a great impact on the results presented above. In particular, studies have been lead by the collaboration to evaluate the influence a 25 G magnetic field on the optical modules, as well as on the event reconstruction [9][18].

SuperNEMO PMTs are protected from the external magnetic field by individual, cylindrical, iron shields. Unfortunately, the latter do not perfectly protect the PMTs, and a residual magnetic field is measured inside the shieldings, leading to charge losses close to 8%, and the energy resolution would be increased of $\sim 3\%$. Moreover, the PMTs shieldings could themselves severely impact the shape of the field lines, as well as its strength. In fact, with a 25 G magnetic field generated by the copper coil, the magnetic shields are responsible for the field strength decreasing, and barely 10 G is expected near the source foils. Worse, the magnetic field strength decreases very quickly as we get closer to the calorimeter walls where nearly 0G could be expected. The reconstruction efficiency could therefore be greatly impacted: the magnetic field intensity varying from the source foils to the calorimeter wall, electrons trajectory curvatures are not constant, and the track-fitting algorithm is less performing. And this effect is higher as the electron energy decreases.

In the light of these conclusions, it could be interesting to study the evolution of the sensitivity, considering field simulations with more realistic variations inside the detector.

7.5.4 Simulations with a non-uniform magnetic field

Simulations with a 25 G mapped magnetic field have been performed, taking into account more realistic variations of the field inside the detector [19]. Unfortunately, not all isotopes could be simulated with this magnetic field configuration. In

particular, radon, as it is present in the entire wire chamber, would have required too many computing resources. Thus, final conclusions on the sensitivity can't be given. However, it is possible to assess the selection efficiencies of the different processes, and thus get an idea of the influence of realistic variations of the field on the final results.

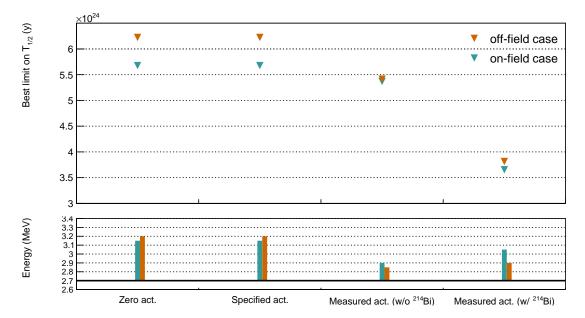

Figure 7.11: Best limit set on $0\nu\beta\beta$ half-life (top pad), and the corresponding ROI (bottom pad), as a function of the contamination level considered, for both on-field and off-field cases.

	Selection efficiencies (%)

7.6 Searching for the Neodymium-150 $0\nu\beta\beta$ decay

This study was conducted jointly with the PhD student Axel Pin, from CENBG [20]. Although we both worked on the whole of the analysis, I presented

in detail, in the previous sections, the results regarding the influence of the magnetic field. Meanwhile, Axel Pin present in detail the possibility of changing the Selenium material by other $\beta\beta$ isotopes. Indeed, on the model of the NEMO-3 detector, which housed 6.914 kg of ¹⁰⁰Mo and 0.932 kg of ⁸²Se, the SuperNEMO detector has the technical possibility of exchanging the source material and study several $\beta\beta$ isotopes. In the case SuperNEMO demonstrates the feasibility of a large-scale tracko-calo experiment, it would be natural to evaluate the sensitivity of SuperNEMO to the $0\nu\beta\beta$ decay of other isotopes than ⁸²Se.

7.6.1 Other possible isotopes

As explained in Chapter 3, the 2.615 MeV γ -ray produced in the decay of 208 Tl is a troublesome source of background. It is then important to select $\beta\beta$ candidates with a $Q_{\beta\beta}$ value above this transition. The natural isotopic abundance is another useful criterion, and typically considering only isotopic abundances greater than 2% is a good basis for making a choice. Five nuclei satisfy these two criteria: 116 Cd, 82 Se, 100 Mo, 96 Zr and 150 Nd (with respective $Q_{\beta\beta}$ values of 2.80, 2.99,3.03, 3.35 and 3.36 keV and respective isotope abundance values of 7.5, 9.2, 9.6, 2.8 and 5.6 % [22]). Given the availability of 100 Mo, much effort has been focused by the NEMO-3 collaboration on this isotope (it had already been studied by the NEMO-2 prototype [21]). As the 150 Nd isotope has the highest $Q_{\beta\beta}$ value, the current section focuses on evaluating the SuperNEMO sensitivity to the $0\nu\beta\beta$ decay of this isotope, supposing we have several kg at our disposal.

7.6.2 Sensitivity to the $0\nu\beta\beta$ of ^{150}Nd

- préciser que compte-tenu du Z important du 150Nd, même si la demi-vie de la 2nu est assez faible, cela ne gêne pas trop car les effets coulombiens font que la 2nu ne contribue pas trop à haute énergie.
- distribution t1/2 avec différents échantillons de simus (17.5 kg.y)
- Qbb élevé donc contributions du Bi et Rn très petites voires nulles donc 2nu et Tl dominent
- eff plus basse pour sélections internes pe à cause du Z plus élevé

7.7 The final detector sensitivity

The final goal of the SuperNEMO demonstrator is to demonstrate that the NEMO technology is scalable to reach high half-life sensitivity on the $0\nu\beta\beta$ decay. It was therefore mandatory to study the case of the final detector sensitivity, consisting in building 20 modules similar to the SuperNEMO demonstrator, to reach unprecedented levels on effective neutrino masses.

7.8 Conclusion

- Plot général récap tous résultats
- manque de stat pour le neodyme car ROI haute E
- légères diff avec résultats axel car légères diff dans sélections d'ev car utilisation PID
- optimisation topo cuts : multivariate analysis peut être envisagée pour aller plus loin
- tenir compte de la dégradation en énergie dans les simus du au B
- cellules tracker dead-¿ refaire analyse
- ouverture sur possibilité d'étudier l'influence de la résolution en temps des PMs sur l'eff des coupures (Pint)
- Etude plus générale avec bkg externe+lab (reprendre chiffres NEMO3) + neutrons (cf NEMO3)
- ajouter possibilité champ mappé
- delayed cells-¿improvement, cf NEMO 3
